Basic Database Query Concepts

Understanding foundational database query concepts is crucial for answering interview questions confidently. This section focuses on fundamental SQL queries, data retrieval methods, and essential database operations.

What is SQL and its types of statements?

SQL, or Structured Query Language, is a standard language used to communicate with relational databases. The main types of SQL statements include:

- **DDL (Data Definition Language):** Statements such as CREATE, ALTER, and DROP that define or modify database structures.
- **DML (Data Manipulation Language):** Commands like SELECT, INSERT, UPDATE, and DELETE used to manipulate data within tables.
- **DCL (Data Control Language):** Statements including GRANT and REVOKE that control access permissions.

- **TCL (Transaction Control Language):** Commands like COMMIT, ROLLBACK, and SAVEPOINT that manage transactions.

Explain the SELECT statement and its basic usage.

The SELECT statement is used to retrieve data from one or more database tables. The basic syntax involves specifying the columns to retrieve and the table name. For example:

```
SELECT column1, column2 FROM table_name;
```

It can be enhanced by clauses such as WHERE for filtering, ORDER BY for sorting, and GROUP BY for aggregation.

What are joins in SQL?

Joins are used to combine rows from two or more tables based on related columns. Common join types include:

- **INNER JOIN:** Returns only matching rows from both tables.
- **LEFT JOIN (or LEFT OUTER JOIN):** Returns all rows from the left table and matched rows from the right table.
- **RIGHT JOIN (or RIGHT OUTER JOIN):** Returns all rows from the right table and matched rows from the left table.
- **FULL JOIN (or FULL OUTER JOIN):** Returns all rows when there is a match in one of the tables.

Advanced SQL Query Techniques

This section addresses more complex SQL queries, including subqueries, set operations, and window functions that often appear in database query interview questions and answers.

What is a subquery and how is it used?

A subquery, or nested query, is a query within another SQL query. It is used to perform operations that require intermediate results, often in WHERE, FROM, or SELECT clauses. For example:

```
SELECT employee_id, name FROM employees WHERE department_id IN (SELECT department_id FROM departments WHERE location = 'New York');
```

Subqueries can be correlated or uncorrelated depending on whether they reference columns from the outer query.

Explain the use of GROUP BY and HAVING clauses.

The GROUP BY clause groups rows that have the same values in specified columns into summary rows, often used with aggregate functions like COUNT, SUM, AVG, etc. The HAVING clause filters groups based on a condition, unlike WHERE which filters rows before grouping.

Example:

```
SELECT department_id, COUNT(*) FROM employees GROUP BY department_id HAVING COUNT(*) > 5;
```

What are window functions and why are they important?

Window functions perform calculations across a set of rows related to the current row without collapsing the result set. They are useful for running totals, ranking, moving averages, and more. Common window functions include ROW_NUMBER(), RANK(), and LAG().

Query Optimization and Performance Tuning

Efficient query execution is vital in real-world applications. This section explores strategies and concepts related to optimizing database queries, a frequent topic in database query interview questions and answers.

What is indexing and how does it improve query performance?

Indexing creates a data structure that improves the speed of data retrieval operations on a table at the cost of additional writes and storage space. Indexes allow the database engine to find data quickly without scanning the entire table. Types of indexes include:

- B-Tree Indexes
- Bitmap Indexes
- Unique Indexes
- Composite Indexes

How to identify and fix slow-running queries?

Slow queries can be diagnosed using tools like EXPLAIN plans which show how the database executes a query. Common optimization techniques include:

1. Adding appropriate indexes
2. Rewriting queries to reduce complexity

3. Avoiding SELECT *
4. Using joins instead of subqueries where possible
5. Limiting result sets with WHERE clauses

Explain the concept of query execution plan.

A query execution plan is a detailed roadmap generated by the database engine that shows the steps taken to execute a query. It helps in understanding how tables are scanned, joins are performed, and indexes are utilized. Analyzing execution plans is a key skill for database tuning.

Transaction Management and Control

Handling transactions correctly ensures data integrity and consistency, topics that often appear in database query interview questions and answers.

What are database transactions?

A database transaction is a sequence of operations performed as a single logical unit of work. Transactions must be atomic, consistent, isolated, and durable (ACID properties) to maintain database integrity.

Explain COMMIT and ROLLBACK commands.

COMMIT saves all changes made during the current transaction to the database permanently, while ROLLBACK undoes all changes made during the current transaction, reverting the database to its previous state.

What is isolation level in transactions?

Isolation levels define the degree to which a transaction must be isolated from data modifications made by other transactions. Common isolation levels include:

- Read Uncommitted
- Read Committed
- Repeatable Read
- Serializable

Higher isolation levels reduce concurrency but increase data consistency.

Common Interview Scenarios and Problem Solving

Practical problem-solving questions are a significant part of database query interview questions and answers. This section covers typical scenarios and approaches to tackle them.

How to write a query to find duplicate records?

Identifying duplicate records involves grouping data on key columns and filtering groups having more than one occurrence. Example:

```
SELECT column_name, COUNT(*) FROM table_name GROUP BY column_name HAVING COUNT(*) > 1;
```

Write a query to fetch the second highest salary from the employees table.

Several methods exist, one common approach uses the DISTINCT and LIMIT clauses or subqueries:

```
SELECT MAX(salary) FROM employees WHERE salary < (SELECT MAX(salary) FROM employees);
```

How to update records based on a condition involving another table?

Using UPDATE with a JOIN or subquery allows modifying records conditionally. Example:

```
UPDATE employees SET salary = salary * 1.1 WHERE department_id IN (SELECT department_id FROM departments WHERE location = 'Chicago');
```

Frequently Asked Questions

What is the difference between INNER JOIN and LEFT JOIN in SQL?

INNER JOIN returns only the rows that have matching values in both tables, whereas LEFT JOIN returns all rows from the left table and the matched rows from the right table; if there is no match, NULLs are returned for columns from the right table.

How do you optimize a slow-running SQL query?

To optimize a slow-running query, you can analyze the query execution plan, create appropriate indexes, avoid using SELECT *, filter data early with WHERE clauses, minimize joins and

subqueries, and consider query rewriting or denormalization if necessary.

What is a primary key and can it accept NULL values?

A primary key is a column or set of columns that uniquely identifies each row in a table. It cannot accept NULL values because it must uniquely identify every row.

Explain the concept of normalization and its types.

Normalization is the process of organizing data in a database to reduce redundancy and improve data integrity. Common normal forms include 1NF (eliminate repeating groups), 2NF (remove partial dependencies), 3NF (remove transitive dependencies), and BCNF (Boyce-Codd Normal Form) for stricter rules.

What is the difference between WHERE and HAVING clauses?

WHERE clause is used to filter rows before grouping, applied to individual rows, while HAVING clause is used to filter groups after aggregation, applied to aggregated data.

How would you find the second highest salary from an employee table?

One way is using a subquery: `SELECT MAX(salary) FROM employees WHERE salary < (SELECT MAX(salary) FROM employees);` alternatively, use `ORDER BY salary DESC` with `LIMIT` and `OFFSET` depending on the SQL dialect.
